Abstract

Weed infestation of horticultural crops in gardens, parks, and orchards has become a menace bedeviling the productivity of fruits and vegetables. Nutgrass (*Cyperus rotundatus* L.) is one of the weeds found on horticultural farms whose leachates and exudates influence the performance of crops grown in farms and orchards on different soils. Paw paw is a common orchard crop grown for commercial purposes in the tropics with intense economic returns. This study investigates the allelopathic effects of nutgrass extracts (50g/cm³, 100g/cm³, 150g/cm³, 200g/cm³, 300g/cm³, and control) in different soils (sandy, loamy, clayey, and silty) on the seedling growth of paw paw (*Carica papaya* L.) in a split-plot experiment replicated 3 times. The study unveiled that with increased concentration of nutgrass extract, the growth performance of pawpaw seedlings significantly declined. Similarly, the soils with better porosity, high water-holding capacity, as well as high nutrient retention (such as loamy and silty soils) support better seedling performance in pawpaw. It is therefore noted that to reduce the allelo-effect of decomposing leachates and exudates from weeds (nutgrass) on farms, regular weeding and complete destruction and removal of weeds (nutgrass) around the base of paw paw plants in orchards is recommended. Sandy soil has less effect on allelic activity of nutgrass than other heavy soils.

Acknowledgements

I appreciate the support of the Tertiary Education Trust Fund (TETFund) through the IBR intervention for providing the necessary funds to conduct this research. The support of the Federal Polytechnic Mubi in providing the necessary enabling environment is highly appreciated.

Introduction

Pawpaw (*Carica papaya* L.) is an important agricultural export crop for developing countries; the export revenues of the fruit provide a livelihood for thousands of people and contribute to the growing supply of healthy food products in international markets. Its production was estimated at 11,223,031 metric tons (t), including 713,800 t from India (38.61%), 1,871,300 t from Brazil (17.50%), 703,800 t from Nigeria (6.79%), Indonesia (695,214 t), Mexico (616,215 t), and Ethiopia (232,400 t) (Olusegun et al., 2016). Other countries

involved in commercial pawpaw production are Sri Lanka and Tanzania (Belel & Belel, 2015). These estimated production values were, however, influenced by many environmental factors in the field, including the allelopathic exudates from associated weed species that commonly grow in pawpaw farms. Allelopathy refers to the beneficial or harmful effects of one plant on another plant, both crop and weed species, from the release of biochemicals, known as allelochemicals, from plant parts by leaching, root exudation, volatilization, residue decomposition, and other processes in both natural and agricultural systems (Belel & Belel, 2015). There is also a growing interest in harnessing the potential of allelochemicals for weed management, as weed infestations significantly affect both the quantity and quality of crop yields (Pervin & Rabeya, 2024). Nutgrass is a common tropical weed that is found growing in both nurseries and in the field. The different soil types to which organic residue from decomposing vegetation of nutgrass may give varying reactions due to differences in either their physicochemical composition or their response to phytochemical exudates in the decomposing residue, which may affect seedling germination or growth. Many crops and root residues have been reported to have allelopathic effects on agricultural plants (Whittaker & Feeny, 1971; Price et al., 2008). Previous studies of the effects of allelopathy on the performance of certain crops by exudates from leaves, flowers, stems, fruits, or roots of weed species were reported by many researchers. Belel and Rahimatu (2012) reported on seed and leaf extract on groundnut; Belel and Belel (2015) reported on allelopathy due to seed and root exudates in beans.

| Statement of the Problem

Despite several studies reported on allelic relations involving cereals, legumes, and medicinal crops, there is little or no literature on allelopathy as it affects vegetables and fruits, especially in the tropical humid climate. Information on the allelopathic relationship between pawpaw and common weeds such as nutgrass is yet to be explored, especially at the germination and seedling growth level.

| Objectives of the Study

This study therefore seeks to understand the effects of different concentrations of extract from the leaves of nutgrass in different types of soil on the germination and seedling growth of pawpaw, with a view to improving the productivity and value of the crop at its early stages of life.

| Literature Review

These allelopathic chemical compounds are released by living organisms and have an influence on the health and survival of other living things (Iqbal et al., 2020). These allelochemicals are released under certain conditions, and they have an impact on both soil bacteria and other plants in the vicinity, influencing seed germination, root and stem growth, and other plant functions (Yu et al., 2003; Iqbal et al., 2020). The production of these compounds is highly influenced by different phases of plant growth, genetics, and environmental variables (Yu et al., 2003). A large number of plants impose inhibitory effects on the germination and growth of neighboring or successional plants by releasing allelopathic chemicals into the soil, either as exudates from living tissues or by decomposition of plant residues (Khan et al., 2009). Allelopathy plays an important role in many agroecosystems (Singh et al., 2008). Most of the initial work performed with laboratory bioassays of allelochemicals had generally focused on seed germination and seedling growth (Oraon & Mondal, 2020). The utilization methods of growth response and biochemical effects (allelopathy) are equally interested in poor germination and growth of vicinity vegetation (Singh et al., 2008; Pezzopane et al., 2021). Some studies have shown an inhibitory effect of aqueous extracts at different concentrations on seed germination and seedling growth compared to the control (Soleymani & Shahrajabian, 2012; Shahid et al., 2017).

Methodology

The Study Area

The study was conducted in both the Crop Science Laboratory and the orchard farm of the Horticultural Technology Department of Federal Polytechnic, Mubi. Mubi is the headquarters of Mubi-North Local Government, which is located on latitude 10°15'N and longitude 13°16'E at an altitude of 696 m above sea level. The climate is characterized by alternating dry and wet seasons. The rains last from April to October, with a mean annual rainfall of 700 to 1050 mm (Udo, 1970; Adebayo, 2004).

Sample Preparation

Fresh samples of the weed plant (*Cyperus rotundatus*) were collected from agricultural fields in Federal Polytechnic Mubi. The leaves of *Cyperus rotundatus* were collected and removed from the plant and washed several times with running tap water, then rinsed with distilled water. The leaves were then dried in the oven at 80°C for 24 hrs, and the dried samples were then ground to powder form.

Preparation of Extract

The plant samples that were collected were washed with tap water, followed by several washings with distilled water. The leaves were placed into the hot air oven at 80°C for 24 h for drying and sterilization. This was then transferred into a sterilized motorized blending machine for grinding to a fine powder. The ground samples were then sieved through an 8.0 mm size wire mesh net, and the larger particles were removed. The fine particles were weighed into 50 g, 100 g, 150 g, and 300 g by using a digital weighing scale. Each of the sieved powdered samples was then dissolved into 100 cm³ of distilled water to make up the various concentrations and was left for 24 h. The concentration was then filtered by using a funnel and muslin cloth into various conical flasks. The concentrations of 0.5 g/cm³, 1.0 g/cm³, 1.5 g/cm³, 2.0 g/cm³, and 3.0 g/cm³ were obtained after filtration. The various concentrations were then ready for germination and seedling growth tests.

Experimental Set Up

The field experiment was conducted at the orchard farm of the Department of Horticultural Technology using the split-plot design involving a control plot and five concentrations of *Cyperus rotundatus* leaf extracts as the main factor. Seventy-two polythene bags filled with different soil types (sandy, clayey, loamy, silty) as sub-factor were used. Five seeds each of pawpaw were planted in each polythene bag that was filled with equal volumes of different soils. Five (5) mls of the leaf extracts at different concentrations were added to the different soils in the polythene bags, and distilled water was added for the control polythene bag. The treatments were replicated three times. The germination and seedling growth of each treatment were recorded on a weekly basis for 2 months. The germinated seeds were counted immediately after germination, while the plant height, number of leaves, tap root width, and total root length were measured. The results were expressed in terms of the average of the treatments in the three replicates.

Statistical Analysis. The data that were obtained from the experiment were analyzed statistically by subjecting them to analysis of variance (ANOVA) of Gomez and Gomez (1984) using the SAS system for Windows. Significant differences among means were separated using the Least Significant Difference (LSD) procedure (Little & Hills, 1986).

Result and Discussion

The alleopathic effect of different concentrations of nutgrass extract and soil types on the days to germination, establishment count, and the heights of pawpaw seedlings are presented in Table 1 below.

Concentrations of nutgrass extract significantly increased the number of days to seed germination. The higher the concentration of extract, the more the number of days it took the seed to germinate. This shows that the allelochemicals in the nutgrass extract may have retarded the process of imbibition by the seed and

thereby delayed germination. However, 50g/cm³ and 150g/cm³ seem to respond significantly faster in germination compared to higher concentrations of nutgrass extract, but later when compared to the control plot. Similarly, the response of days to germination on different soil types showed highly significant germination, with silty soils providing faster germination compared to other soils. Except for silty soil, all other soils recorded the same number of days to germinate.

Furthermore, establishment count was highly different, with decreasing numbers of seedlings as the concentration of nutgrass extract increased. The control plot, as well as the 50g/cm³ treatment, gave better established seedlings. The higher concentration of 300g/cm³ had the least number of established seedlings. Clayey soil had a lower number of established seedlings compared to all other soils. This may likely be due to the compacted nature of the clayey soil particles.

Also, the height of seedlings from weeks 1 to 6 is presented in Table 1. Seedling heights were retarded with increasing concentration of extract from weeks 1 to 3 as compared to the control treatment. However, at week 4 there was no difference in height for all concentrations of extracts. This may be due to adaptation to the environment and intense physiological activities by seedlings in all treatments. However, at weeks 5 and 6, the trend of reduced seedling heights intensified with increased concentration of extract. The control treatment as well as 50g/cm³ were the same at weeks 5 and 6 and were taller than all treatments in week 5.

The height of seedlings in different soils also showed that seedlings grew taller in sandy soils in weeks 1 to 5, but seedlings growing in clayey soil tended to maintain the same height as taller sandy seedlings at weeks 2 and 3. There was no significant difference in height among seedlings at weeks 4 and 6.

The interaction between nutgrass and soil in days to germination, establishment count, and plant height at weeks 1, 2, 3, and 5 (Table 1) shows that both nutgrass extract and soil type can significantly improve the performance of pawpaw seedlings if the observed allelopathy is properly managed while taking cognizance of the prevailing soil conditions that favor pawpaw production. The root exudates from pawpaw plants and the leachates from dropping pawpaw leaves may equally counteract the allelopathic potentials in the weeded nutgrass in the soil. The relationship between nutgrass and soil at weeks 4 and 6 is not significantly different.

Table 2 below presents the Allelopathic effect of nutgrass extract and soil type on the number of leaves of pawpaw seedlings from week 1 to week 6.

At week 1, there was significant effect of both nutgrass extract as well as soil type on the number of leaves produced by seedlings. However, at week 2, the higher concentration of extract gave more leaves than the control treatment. The trend of leaf production fluctuates between concentrations, but each varies highly significantly from the other. This pattern is unpredictable and may be associated with fluctuating soil climate. Also, at weeks 3 to 6, the trend of leaf production stabilized among treatments with a significant reduction compared to the control treatment as the concentration of extract increased.

The soil effect on the number of leaves showed more leaves in seedlings grown on loamy soil at week 2, which drastically reduced in week 3. The number of leaves is not significantly different among soils in weeks 4 and 6. The trend in week 5 indicates loamy and silty soils produced the same number of leaves compared to both sandy and clayey soil.

The significant interaction between nutgrass extract and soil type on the number of leaves at weeks 2, 3, and 5 can equally be attributed to both leachates and exudates from pawpaw leaves and roots, as well as the corresponding soil reactions during their relationship in the rhizosphere. Soil has an important role to play in organic matter decomposition. The interactive relationship between soil and nutgrass extract is not significantly different at weeks 1 and 4.

Note: ** = Highly significant, MSD = Minimum significant difference, g/cm³ = grams per centimeter cube, No. = number, values with different letters within a column are significantly different ($P > 0.05$).

The effects of both nutgrass extract and soil type on leaf length, petiole length, total root length, and tap root thickness of pawpaw seedlings are presented in Table 3 below.

The average length of pawpaw leaf at week 6 decreased with increased concentration of nutgrass extract. The different concentrations significantly reduced the length of the leaf at each level of comparison, revealing a progression in the impact of extract concentration on leaf length. However, for the soil impact, seedlings grown on sandy soils produced longer leaves compared to other soils. The leaves of seedlings grown on loamy and clayey soils are moderate and the same in length. Silty soils gave shorter leaves.

Petiole length at week 6 exhibited a similar growth pattern to leaf length. Petioles became shorter with increased concentration of extract. The soil effect on petiole length depicts longer petioles in seedlings grown on sandy soils, while shorter petioles were recorded on seedlings grown in loamy and silty soils.

The total root length of pawpaw seedlings at weeks 3 and 6 (Table 3) showed better root development with reduced concentration of nutgrass extract at both weeks 3 and 6. The soil effect also indicates longer roots in sandy and loamy soils. This may likely be due to high porosity of these soils allowing easy access for root penetration in both micro and macropores in the soil. Silty soil gave shorter roots at week 3.

Tap root thicknesses are not significantly different in both weeks 3 and 6 for both nutgrass extract and soil type (Table 3).

The soil is the environment for root growth and development. In the interaction between nutgrass extract and soil type on root length as well as tap root thickness, which is shown to be highly significant for pawpaw root growth, the antagonizing allelopathy that may be found in soil due to products of decomposition of litter of pawpaw leaves and other weeds may create a balance in the rhizosphere. This will support bacterial activity for better crop growth. Petiole length and leaf length also have a better interaction between nutgrass extract and soil type (Table 3).

Conclusion

Allelochemicals from the leaves of weeds growing in orchards and gardens have been known to affect the productivity of crops. Now that efforts are being made to understand the concentration at which they exert more effects, this work unveiled the relationships between nutgrass and pawpaw in different soils. It showed that with increasing concentration of extract, growth performance of pawpaw declines. The growth of seedlings of paw paw is affected at all concentrations of nutgrass extracts. Also, light soils (sand and silt) tend to support seedling growth better than heavy soils such as clay and loam.

Recommendations

Findings from this study suggest that allelopathy in extract of nutgrass can affect the performance of pawpaw irrespective of concentration. It is therefore recommended that while growing pawpaw in plantations or orchards, the crop-weed relation should have zero tolerance, especially at the base of the growing seedlings. Similarly, pawpaw seedlings should be managed in light soils such as sand and silt.

Conflict of Interest

It is hereby declared that there is no conflict of interest among the authors of this work.
